Problem Statement

Retinal vessel image segmentation is a pivotal challenge in medical image analysis, integral to early disease diagnosis, disease progression monitoring, and personalized treatment planning for conditions like diabetic retinopathy and glaucoma. The goal is to leverage classical machine learning methods to precisely identify and isolate blood vessels in retinal images. The complexity arises from the lower contrast in vascular structures and the need to address challenges such as noise and uneven illumination. The project aims to enhance the accuracy and efficiency of retinal vessel segmentation, contributing to improved medical diagnostics and personalized care.

Generated CLAHE Histogram

Dataset & Existing Analysis

DATASET DESCRIPTION

The CHASEDB1 dataset comprises 28 retinal images, representing both eyes of 14 participants. Each image is accompanied by two ground truth annotations ("1stHO" and "2ndHO") from different human observers, totaling 84 images. The file naming convention includes participant numbers (01-14), eye identifiers (L/R), and ground truth sources. This dataset is vital for training and evaluating retinal vessel segmentation models.

EXISTING ANALYSIS

01

Stages of Current Study

Pre-processing: Enhance vessel visibility by addressing noise and uneven illumination.

Vessel Segmentation: Identify and extract retinal vessels.

Post-processing: Remove unwanted elements separate connected vessels.

02

Challenges

Vascular structures in retinal images **exhibit lower contrast.**

Anatomical features may lack clear characteristics.

Classical segmentation techniques are often inefficient and inaccurate.

03

Recent Techniques

Supervised:

- Support Vector Machines (SVMs)
- AdaBoost:
- KNN's

Unsupervised:

- Matched Filters
- Morphological Processing
- Thresholding

EDA & Pre-Processing

Green Channel Isolation

Green channel is isolated and focused during segmentation as it exhibits superior contrast between the vessels and the background.

Contrast Limited Adaptive Histogram Equalization

CLAHE is a technique that improves contrast in images by limiting amplification in local areas and adjust image contrast using pixel intensity based histogram.

Gamma Correction

Gamma correction is a technique used in image processing to adjust the brightness of an image by modifying the intensity values of its pixels to enhance and reduce image contrast.

Gamma Correction

Methodology - Page 1

1. Hessian Matrix and Eigenvalue Approach:

- **Description:** The Hessian matrix, a square matrix of second-order partial derivatives, is utilized to study the local behavior of a function in retinal vessel segmentation.
- **Application:** Enhances and detects vessel structures in retinal images by understanding the curvature and critical points.

2. Gabor Filter :

- **Description:** A Gabor filter is a specialized tool for image processing, adept at detecting edges and textures of different orientations and frequencies.
- **Application:** Used to identify and separate different regions of interest, such as the optic disc, blood vessels, and other anatomical structures in retinal images.

3. Binary and Otsu Thresholding

- **Description:** Image processing techniques employed to segment images by separating objects from the background based on pixel intensity values.
- **Application:** Enhances contrast, extracts specific structures like blood vessels, and automates the segmentation process in retinal images.

Methodology - Page 2

4. Local & Pixel Based Thresholding:

- **Description:** Pixel-based thresholding applies a uniform threshold to the entire image, while local thresholding adapts the threshold based on local characteristics.
- **Application:** Distinguishes between different objects or regions, with local thresholding providing adaptability to variations, crucial for identifying blood vessels accurately.

5. Image Fusion:

- **Description:** Image fusion is a technique for improving image quality and information content by combining complementary information from multiple sources. Here, our goal of using image fusion is to fuse the image that we got after the Otsu thresholding (representing the thick vessel), and the second image that we got by normalizing the image of the thin vessel, to get the finest image.
- **Application:** Enhances the quality and richness of retinal images by fusing diverse information, contributing to the accuracy of vessel segmentation.

6. Wide and Thin Vessel Enhancement:

- **Description:** Applied to Hessian-enhanced images for retinal vessel segmentation, Otsu's Thresholding automatically determines an optimal threshold by maximizing variance between classes (vessels and non-vessels).
- **Application:** Segments vessels from the background with adaptability to varying image characteristics, ensuring accurate and automated segmentation.

Results

The implemented methodology for retinal vessel image segmentation achieved the following results:

1. Accuracy:

- The segmentation process yielded an accuracy of about **95%**, reflecting the effectiveness of the devised methodology in accurately identifying and isolating retinal vessels.

2. Structural Similarity Index (SSI):

- The Structural Similarity Index measure, a metric assessing the similarity between the ground truth and segmented images, provided a value of **0.87**.
- An SSI value of 1 indicates perfect similarity, and 0 denotes no similarity. The achieved value suggests a substantial degree of structural similarity between the ground truth and segmented images.

3. Peak Signal-to-Noise Ratio (PSNR):

- The Peak Signal-to-Noise Ratio, measuring the quality of the segmentation by evaluating the ratio of the maximum possible power of a signal to its noise, was approximately **55**.
- Higher PSNR values indicate better image quality, reflecting the accuracy and fidelity of the segmented vessel structures.
